

THE NATURAL BEHAVIOR OF *DROSEREA*:
SUNDEWS DO NOT CATCH INSECTS ON PURPOSE

Keywords: carnivory: *Drosera anglica*, *D. rotundifolia* – field studies: *Drosera anglica*,
D. rotundifolia.

Abstract

The trapping behavior of carnivorous plants has attracted attention of naturalists for almost two centuries. With the most observations made in laboratories, the behavior of sundew *in situ* has not been studied enough. We observed *Drosera* leaf behavior in natural habitats with non-manipulative technique. Three leaf characteristics for two species (*D. rotundifolia* L. and *D. anglica* Huds.) from two regions (6 plants with 30 leaves) were continuously observed during 196 hours. Our observations show that changes of the leaf characteristics of two sundew species in nature are almost casual and likely only corrected by external factors such as relative air humidity and presence of fresh prey (“semi-accidental feeding”). We consider trapping leaves of the two studied *Drosera* species as transitional structures between active and passive fly-paper traps.

Introduction

The origin and evolution of carnivory is an important and challenging topic in evolutionary ecology (Benzing 1987). However, the origin of carnivory can hardly be studied in animals since this group is likely ancestrally carnivorous (Nielsen 1995). Carnivorous fungi and plants are more applicable for that research. Among the carnivorous plants, sundews (*Drosera*, Droseraceae) represent an interesting example where, according to experimental data and morphology of some species, both active active and passive prey catching are possible (Juniper *et al.* 1989).

Most of the research of sundew behavior have been done in laboratories, from the early studies (Kellerman & Raumer 1878; Busgen 1883) to those conducted in recent times. Experiments usually show that, for some species of sundews, if prey provides sufficient stimulation, all leaf tentacles bend inwards and cover the prey with an enzyme-containing slime. Upon stimulation with the prey, there is a (1) rapid movement of tentacles in the first 10-30 seconds after touching and (2) slow movement by tentacles that were not at first in contact with prey. This slow movement is observed within first hour after initial contact (Hooker 1916). Juniper *et al.* (1989) state that sundews also secrete a slime just as the prey is captured. After the initial slime secretion, the edge of the leaf blade slowly bends and covers the captured prey. When the digestion process has ended, the leaf blade unwraps, the tentacles straighten and the slime dries (Hooker 1916).

Unfortunately, only several uncoordinated short observations on sundews (Treat 1873; Canby 1874) were conducted in natural habitats. Therefore, the differences between laboratory, artificial conditions, and conditions *in situ* may affect the observations. For example, factors such as weather (Gomez 1998), edaphic conditions, prey amount available, type of prey, and kleptoparasitism by ants (Thum 1989a) cannot properly be taken into account in the indoor experiments.

Several observational strategies are available for outdoor experiments. We choose the most non-manipulative one which is referred below as “continuous observations”. The team of observers recorded

several parameters every 30 or 40 min. All watchers were trained to make consistent observations. The first review of results from one species (*D. rotundifolia*) already suggested that the *in situ* natural behavior of sundews may be radically different from laboratory behavior (Volkova & Shipunov 2005). However, at that time we did not process our data statistically, and all observations were restricted to one species.

Different sundew species may differ in feeding behavior. As an example, significant inter-specific differences of prey amount that remained on the leaf in 24 hours were revealed in the field experiments (Thum 1988, 1989a,b) with artificial feeding of trapping leaves of *D. rotundifolia* and long-leaved *D. intermedia* Hayne. Mire ants carry away about two thirds of prey from trapping leaves of *D. rotundifolia*, while prey on the leaves of *D. intermedia* remain almost untouched (Thum 1989b). *Drosera rotundifolia* is reported to catch three times more prey than *D. intermedia* (Thum 1989a,b). In the north of European Russia, *D. rotundifolia* grows together with *D. anglica*, another long-leaved sundew species that is similar to *D. intermedia* both morphologically and ecologically (Webb 1993). Therefore, *D. anglica* seems to be a good choice for expanding our methods to a larger number of species. We also decided to process our data in a much more detailed way than in our previous work (Volkova & Shipunov 2005).

Materials and Methods

To expand the taxonomic coverage of our research, we observed plants of *D. anglica* in natural habitats in Loukhi district of Karelia republic (Northern Karelia, European Russia) on July 16-18, 2005. Plants were growing on the *Sphagnum* mire on the shore of an unnamed lake (N66° 18.5', E33° 07.5'), and were chosen randomly from a typical population. Each of two chosen plants possessed 7 trapping leaves, therefore there were 14 observational units. Continuous observations for these two plants lasted for 52 hours. At 40 minute intervals we recorded (1) secretion degree, (2) bending degree of marginal tentacles, and (3) shape of each leaf (Volkova & Shipunov 2005; see also Table 1). We also counted the number of prey units on the leaf blade and measured relative air humidity with a common digital psychrometer located nearby.

Observation *in situ* is usually a challenge. In particular, we did not use video cameras since it is hard to organize work with cameras in a non-threatening way. Instead, we employed teams of observers. To avoid problems involved with human observers, each team was trained to reach the satisfactory level of consistency. All teams employed in 2000, 2002, and 2005 were led by the same supervisors who controlled quality of observations. The scales (Table 1) were designed to be simple enough, which eased the learning curve.

For the analysis, we also used data from our observations on *D. rotundifolia* (Volkova & Shipunov 2005). These observations were performed in North Karelia (nearby location) in 2000, and in Tver region (Middle Russia) in 2002. In all, 4 plants and 16 observational units were observed. Observations in North Karelia and in Tver region continued for 72 hours each (once in approximately 40 min and once in 30 min respectively).

For each leaf in the *D. anglica* and *D. rotundifolia* data, we created graphs of changes of all the three leaf characteristics during the observation time. The most typical graphs are presented in Figures 1-3.

All data were analyzed mostly with non-parametric statistical methods. Leaf reaction to the prey was examined using Wilcoxon tests, comparing the characters of leaf in the moment of prey capture and in the given time shift (0.5, 1, 2, and 3 hours). Wilcoxon tests were also employed to compare the observed leaf behaviour with the expected behaviour, predicted from the literature data of indoor experiments (Hooker 1916; Juniper *et al.* 1989), and to compare leaves with the absence of prey with leaves having the prey after 1 h interval. Concordance of changes of different characters of the given leaf as well as concordance between leaves of one plant was checked with Spearman correlation test. This test was also employed to reveal the dependence of different leaf characters on air humidity. Chi-square tests were used to understand the significance of the amount of leaves with characteristics unexpected from the literature. Finally, ANOVA were used for revealing the relationship between leaf characteristics and air humidity, for analysis of the dependence between time shift and leaf characteristics, and for the analysis of coordination between different leaves of the same plant.

Figure 1: Changes in the degree of bending of marginal tentacles of model *Drosera* leaves. The times of arrival of the fresh insect on the leaf blade are shown with filled circles.

Figure 2: Changes in the degree of secretion of model *Drosera* leaves, compared with changes of relative air humidity. Relative air humidity (right Y-axis) is shown with the dotted line (not available for *D. rotundifolia* in Northern Karelia). The times of arrival of the fresh insect on the leaf blade are shown with filled circles.

Figure 3: Changes in the shape of the model *Drosera* leaves. The times of arrival of the fresh insect on the leaf blade are shown with filled circles.

Differences between feeding strategies of *D. rotundifolia* and *D. anglica*, revealed by visual inspection of our data (Table 1), were illustrated with PCA (principal component analysis) of averaged behavior for all three species/region groups plus the “ideal” sundew (imaginary plant with maximal values of leaves characteristics in 1 hour after prey catching).

For statistical analyses and graph creation, R environment for statistical computing was used (R Development Core Team 2007).

Results

A significant number of trapping leaves did not react to the prey in one hour: from 52% for *D. rotundifolia* in North Karelia to 29% for the same species in Tver region (45% for pooled data). These proportions were significantly different from the expectation of 95% change (Chi-square test $p \ll 0.05$ for all four cases). In next two hours, leaf conditions did not change significantly: ANOVA analysis for 0.5, 1, 2, and 3 hour time shifts did not reveal any significant dependence between time and leaf characteristics (in all three cases $p \gg 0.1$). In general, there were no significant differences between leaf condition at the moment of prey capture and in one hour later (Wilcoxon $p \gg 0.1$ for all three leaf characteristics). Only degree of secretion, and only for plants from North Karelia demonstrated some significant differences (Wilcoxon $p \ll 0.05$ for both *D. anglica* and *D. rotundifolia* from this region). At the same time, there was an evident relation between the degree of secretion and relative air humidity (see Figures 2 and 4; Spearman $\rho = 0.37$, $p \ll 0.05$; ANOVA $p \ll 0.05$). Degree of bending and shape were correlated with humidity to a much lower extent (Spearman $\rho < 0.1$ in both cases).

Quite often the behavior of leaves was different from that usually discussed in the literature (see Figures 1-3), or “ideal behavior” (to imitate this behavior, we used maximal values of leaf characteristics). As an example, all the leaf characters in 0.5-3 hours after prey capture differed significantly from “ideal” values (Wilcoxon $p \ll 0.01$ for all leaf characteristics).

Leaf characteristics	Scores
Secretion degree	0 – poor, the leaf is almost dry 1 – medium 2 – high, droplets are well-formed
Leaf shape	1 – leaf is almost flat 2 – leaf is almost flexed 3 – leaf is almost bent
Degree of bending	1 – no or few bent tentacles 2 – approximately half of the tentacles are bent 3 – all or almost all tentacles are bent

Table 1: Leaf characters observed.

Characteristics of leaves without prey did not differ significantly from characteristics of leaves that caught prey 1 hour ago (Wilcoxon $p > 0.1$) for all cases except degree of secretion for North Karelian plants (Wilcoxon $p \ll 0.05$). In addition, leaves without prey often had the “wrong” condition: more than 44% of them have all three characteristics that deviated from condition “by default” (Chi-square $p \ll 0.05$).

Changes of different types were not correlated – averaged coefficients of correlation between all the three leaf characters were lower than 0.33 (mean correlation 0.06). The correlation in behavior of all leaves from the same plant was low (Spearman $\rho = 0.25$), but for bending and secretion of leaves belonging to *D. rotundifolia* from Tver region, values of correlation were higher than 0.4 and significant. Consequently, ANOVA analysis of correlation between years revealed a significant difference ($p \ll 0.05$) whereas no differences in correlation coefficients were revealed from comparison of different characteristics from pooled data (ANOVA $p \gg 0.1$) and from comparison of different plants observed in the same year (Wilcoxon paired signed rank test $p \gg 0.1$).

For *D. anglica* the number of insects caught varied from 0 to 1.4 (0.6 in average) per leaf in a day, while *D. rotundifolia* trapped from 0 to 0.7 insects (0.3 in average) in the Northern Karelia, and from 0 to 3.0 (1.0 in average) in the Middle Russia. PCA analysis of one hour behavior for all three species/region groups revealed that *D. rotundifolia* plants from Moscow region behaved similar to *D. anglica* and *D. rotundifolia* from North Karelia. All three observations were distant from the “ideal” plant which differed from plants observed in nature by all three leaf characteristics. *Drosera rotundifolia* plants from North Karelia demonstrated more developed bending whereas *D. anglica* demonstrated more developed secretion (see Figure 5).

Discussion

In all, our statistical analysis support the conclusion stated in our previous paper (Volkova & Shipunov 2005): secretion, leaf curving, and tentacle bending do not depend on prey capture, and secretion is probably regulated by relative humidity. Our results do not let us speculate about inconsistency between field and laboratory data. One possible reason could be that in artificial conditions sundew plants were simply overfed. Nevertheless, this inconsistency emphasizes the necessity of further investigation of trapping behavior of sundews.

The analysis also showed that differences between regions and between *D. anglica* and *D. rotundifolia* are almost equal. Despite the slightly different tactics, there is much more in common between the two studied *Drosera* species. This similarity could be caused by close genetic relationships between the two species (Rivadavia *et al.* 2003). The absence of correlation between the behavior of trapping leaves and presence of prey let us to consider sundew trapping leaves as a structure transitional between active and passive flypaper traps, whereas the common opinion con-

siders them as active flypaper traps (see, for example, Williams 1976; Heubl *et al.* 2006). Our data also support the recent hypothesis on the facultative role of carnivory in the carnivorous plants (Dore & Maham 1969; Small *et al.* 1977; Stewart & Nilsen 1992; Ellison & Gotelli 2001).

In general, it is possible to distinguish two main stages in every feeding process (Hardys *et al.* 1990): “catching” (binding of food with the feeding organ) and “digesting” (absorption of food). There are transitions between “poor catchers and digesters” as protocarnivorous plants (Spomer 1999) and “perfect catchers and digesters” as carnivorous plants with snap-traps (Heubl *et al.* 2006). Some primitive animals like *Hydra*, or *Eleutheria* appear to be “non-perfect catchers”, but “perfect digesters” (Lasker *et al.* 1982; Hardys *et al.* 1990). According to this classification, the two studied *Drosera* species in the Middle and Northern European Russia, being “non-perfect catchers and digesters”, have a separate feeding type which can be named as “semi-accidental feeding”.

In both non-animal carnivores, nematode-trapping fungi, and carnivorous plants, evolution of feeding structures have many common features (Mueller *et al.* 2004; Li *et al.* 2005; Heubl *et al.* 2006). In particular, primitive passive traps (passive fly-paper and adhesive knobs, respectively) evolved in two directions: perfect passive traps (pitfall traps and three-dimensional networks) and perfect active traps (snap and active flypaper traps and constricting rings). Since the flypaper traps of *Drosera* were likely derived from the ancestral passive traps, we can suppose that transition from passive to active traps happened within the *Drosera* genus, causing our two species with the semi-accidental feeding to be in the middle of this transition.

Acknowledgements: Data were collected during White Sea expeditions of Moscow South-West High School led by Dr. S. Glagolev. We thank Yu. Bykov, M. Lyovina, and K. Markvichyova for their essential help in the field observations and Dr. L. Adamec for his valuable comments on the manuscript. No permits were required to conduct the research described in this paper.
